We clarify an instability of the ground state of the Δ chain against the lattice distortion that increases a strength (λ) of a bond in each triangle. It relaxes the frustration and causes a remarkable gap enhancement; only a 6% increase of λ causes the gap doubled from the fully-frustrated case ($\lambda = 1$). The lowest excitation is revealed to be a kink-antikink bound state whose correlation length decreases drastically with λ increase. The enhancement follows a power law, $\Delta E_{\rm gap} \sim (\lambda - 1) + 1.44(\lambda - 1)^{\frac{2}{3}}$, which can be obtained from the exact result of the continuous model. This model describes a spin gap behavior of the delafossite $YCuO_{2.5}$.

Cooperations between theory and experiment in the field of the low-dimensional quantum spin systems are of greater importance especially in these years, since various new compounds have been synthesized which realize theoretical models.[1] Much interest recently is focused especially on the system with a spin gap. As typical examples, we can consider the spin ladder model,[2] the bond-alternation model,[3] and the Majumdar-Ghosh model.[4]

The ground state of the Δ chain shares common properties with models stated above. Its ground state is the pure singlet-dimer state with two-folded degeneracies. The existence of the excitation energy gap above the ground state is rigorously proven.[5,6] However, strong frustration in this model plays an important role to cause unusual properties in the excited states, i.e., its excitation spectrum is dispersionless (zero-energy mode).[7] This mode contributes to the existence of the additional low-temperature peak in the specific heat.[8,9] One of the authors (T.N.) and Kubo,[10] and Sen et al[11] clarified its elementary excitations and how they contribute to the thermodynamic properties. They found that the properties of the excitation is governed by a kink and an antikink. The dispersionless aspect originates in a localized kink, while an antikink moves as a free particle with an effective mass between two localized kinks. This picture is in a clear contrast with the excitation of the Majumdar-Ghosh model, where both a kink and an antikink are equivalently mobile.[12] Sen et al[11] also pointed out the Δ chain can be a model for the recently discovered delafossite $YCuO_{2.5}$, but the estimated spin gap is about half the one measured in the experiment.

Strongly frustrated quantum spin systems have been attracting, since the interplay of the quantum effects and frustration may lead to an exotic ground state. Our question in this letter is that such a spin gap state caused by strong frustration is whether stable or not against a perturbation. If relaxation of frustration occurs by a small perturbation, it may change the spin gap. A pairwise dimerization on the λ bonds shown in Fig. 1 can be realized by the lattice distortion in this system, if the merit of the gap enhancement overcomes the distortion cost. Therefore we investigate the pairwise-dimerized Δ chain in this letter and clarify its gap behavior. The analyses are based upon numerical diagonalization, the variation and the continuous limit. First, we discuss the ground state and find a parameter region that can be realized in the material, and then we study the excitation. In due course, we will find a remarkable enhancement of the gap due to relaxation of frustration by a small increase of the pairwise bond strength (λ); only a 6% increase of λ causes the spin gap doubled, which is consistent with the gap measured in $YCuO_{2.5}$.

FIG. 1. Shape of the distorted Δ-chain. Double lines indicate the λ bonds.

We consider the following Hamiltonian as a model dimerized by lattice distortion.

$$H = \sum_{n=1}^{N} h_n \tag{1}$$

with

$$h_n = \lambda \boldsymbol{S}_{2n-1} \cdot \boldsymbol{S}_{2n} + \boldsymbol{S}_{2n} \cdot \boldsymbol{S}_{2n+1} + \boldsymbol{S}_{2n-1} \cdot \boldsymbol{S}_{2n+1} \tag{2}$$

Here, N is the number of the triangles in the system, λ is a parameter denoting the dimerization, and $|\boldsymbol{S}| = 1/2$. Figure 1 shows the depicted lattice. In this letter, we mainly consider the parameter λ near the symmetric point $\lambda = 1$.

We numerically diagonalized the above Hamiltonian up to the systems with 28 spins ($N = 14$) under the periodic boundary conditions. The λ dependence of the energy is shown in Fig. 2.

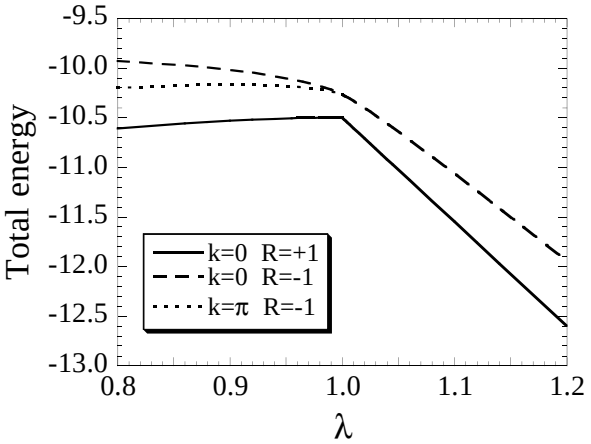

FIG. 2. The λ dependence of the energy of the lowest state in each subspace denoted by k (wave number), and R (spin reversal symmetry) in the system with $N = 14$ (28 spins).

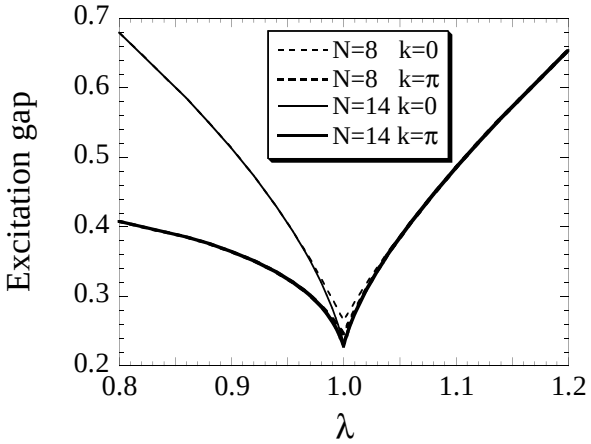

FIG. 3. λ dependence of the first excitation gap in $k = 0$ and $k = \pi$ sector. Sizes of the systems are $N = 8$ and $N = 14$. For $\lambda < 1$, gap in $k = \pi$ becomes smaller than that in $k = 0$.

The phase space is divided into a subspace characterized by eigenvalues of the wave number (k) and the spin reversal symmetry (R) in order to reduce the memory use. From a technical reason, we only diagonalized the space with the wave number $k = 0$ and $k = \pi$, where the ground state and the relevant low-lying excited states are found when $\lambda = 1$. It is noticed that the ground state at the fully-frustrated point, $\lambda = 1$, is most unstable.

The ground state in the case of $\lambda > 1$ is trivial, i.e., the ground of the local Hamiltonian h_n is the singlet dimer state on the λ bond. Direct product of the dimers can span the whole system and be the exact ground state. Thus the total ground state energy is $-0.75\lambda N$. Two excited states shown in the figure degenerate for $\lambda > 1$, which was also observed for higher states. This degeneracy suggests that the excitation is local.

On the other hand, the ground state for $\lambda < 1$ is not trivially solved. It lies in the space of $k = 0$, and the ground state energy gradually decrease with λ go away from 1. A variational analysis and the second-order perturbation analysis manifest that the energy difference begins with the order $(1 - \lambda)^2$. (Details are reported elsewhere.) Therefore the ground state is more stabilized by the perturbation with $\lambda > 1$, which may be actually realized. In this letter, We only discuss the case $\lambda > 1$ in detail, and leave the case $\lambda < 1$ for another opportunity.

Figure 3 shows the λ dependence of the first excitation gap for both $k = 0$ and $k = \pi$ sector. Data of sizes $N = 8$ and $N = 14$ are compared to see the size dependence, as well. Degeneracy between "$k = 0$" and "$k = \pi$" is solved for $\lambda < 1$, and "$k = \pi$" becomes the first excitation. The gap enhancement is remarkably large for $\lambda > 1$. Size dependence is also very weak for λ away from 1. At $\lambda = 1.06$, the gap is about twice the one at $\lambda = 1$.

We consider the following open system to reveal the excited state.

$$H_{\rm open} = \sum_{n=1}^{N} h_n + \lambda \boldsymbol{S}_{2N+1} \cdot \boldsymbol{S}_{2N+2}. \tag{3}$$

We estimate the excitation energy by the following variational analysis. The excited state we consider as the first approximation consists of $(N-1)$ singlet dimers and two free spins. As was done in the previous paper,[10] we name the free spins a kink and an antikink. The wave function of an antikink for an improved approximation may span beyond several spins since the free spin is not an eigenstate of the Hamiltonian. We have considered an antikink consists of 5 spins previously, but it merely increase the effective mass of an antikink and the shape of the wave function are not significantly influenced.[10,11]

We define a variational basis ψ_i so that an antikink is located at the ith triangle.

$$\psi_i \equiv \psi_{\rm kink} \otimes [4,5] \cdots [2i-2, 2i-1]\alpha_{2i} \\ [2i+1, 2i+2] \cdots [2N+1, 2N+2], \tag{4}$$

where $[i, j]$ denotes a singlet dimer state connecting the ith and the jth site, namely $[i, j] = \alpha_i\beta_j - \beta_i\alpha_j$ for $\alpha_i(\beta_i)$ denoting up (down) spin located at the ith site. α_{2i} is an antikink. The wave function of a kink located at the leftmost edge is known as,

$$\psi_{\rm kink} = [\alpha_1(\alpha_2\beta_3 - \beta_2\alpha_3) + \alpha_2(\alpha_1\beta_3 - \beta_1\alpha_3)]/\sqrt{6}. \tag{5}$$

This state is an eigenstate of the local Hamiltonian h_1, and therefore does not move. Its energy eigenvalue is $\lambda/4 - 1$, therefore a kink contributes to the excitation by $(\lambda - 1)$. The singlet dimers that are not on the λ-bonds, existing between a kink and an antikink, are not eigenstates of the local Hamiltonians, h_n. They also contribute to the excited energy.

Variational bases are not orthogonal each other and satisfy the following relations.

$$\langle\psi_i|\psi_j\rangle = \left(-\frac{1}{2}\right)^{|i-j|} \equiv S_{ij} \tag{6}$$

$$\langle\psi_i|H|\psi_j\rangle = \left[E_{\rm g} + (\lambda-1) + \frac{3}{4}(\lambda-1)\min(i,j)\right]\langle\psi_i|\psi_j\rangle + \frac{3}{4}\delta_{ij} \equiv Hij \tag{7}$$

Here, δ_{ij} is the Kronecker delta, and $\min(i,j) = i$ if $i \le j$. The ground state energy $E_{\rm g} = -0.75\lambda(N+1)$. Since the matrix $\hat{S}$ given by eq. (6) is the positive hermitian matrix, we can easily transform this variational problem with the trial function $\Psi_{\rm var} \equiv \sum_i C_i\psi_i$ into the eigenvalue problem of the following Hamiltonian.

$$\hat{H} = (E_{\rm g} + \lambda - 1) + \frac{3}{4}\hat{S}^{-1} + \hat{V} \tag{8}$$

with

$$\hat{V} = \frac{3}{4}(\lambda-1)\hat{S}^{-1/2}\hat{M}\hat{S}^{-1/2}, \tag{9}$$

where $M_{ij} = \min(i,j)S_{ij}$. This can be solved numerically for arbitrary N, say we show the result of $N = 200$ in this letter. Fig. 4 shows the wave function of the lowest eigenstate for $\lambda = 1.00, 1.001, 1.01$.

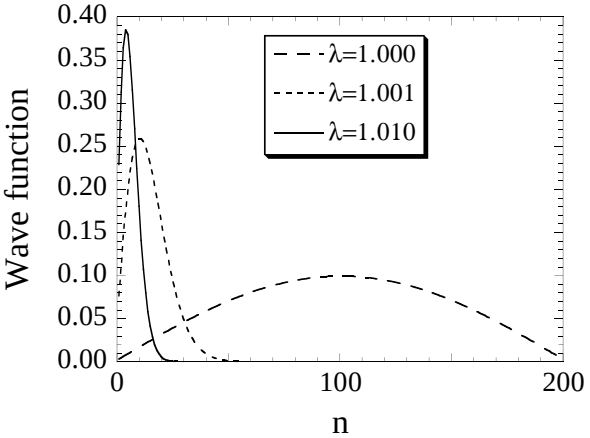

FIG. 4. Variational wave function of the lowest eigenstate for $\lambda = 1.00, 1.001$, and 1.01. Size of the system $N = 200$. n stands for the site number of the triangles.

We find from this figure that an antikink drastically approaches a kink as λ increase from 1.

Fig. 5 shows the behavior of the gap enhancement defined by $E_{\rm gap}(\lambda) - E_{\rm gap}(1)$.

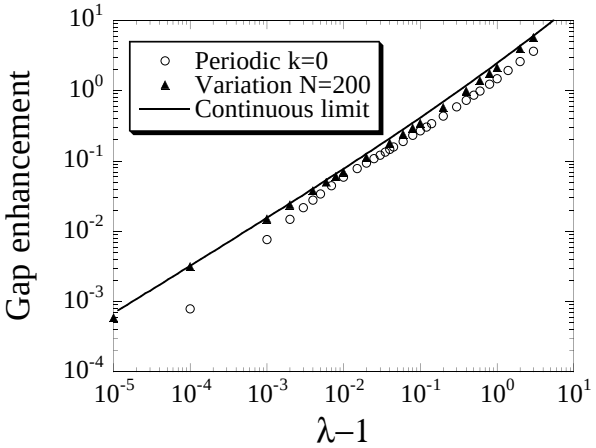

FIG. 5. Log-log plot of the gap enhancement for the variational results of $N = 200$, and the numerical ones after extrapolated $N \to \infty$. We also plotted the exact result in the continuous limit of eq. (12) with the mass $m = 1.21$.

We also plot the gap enhancement of the periodic system after the extrapolation of $N \to \infty$ by using data with $N = 8, \cdots, 14$. Since the variational wave function of $\lambda = 1.01$ only takes a finite value for $n < 20$, as shown in Fig. 4, the finite size treated in the numerical diagonalization is enough to extract the properties of infinite-size system for $\lambda > 1.01$. Contrary to this, data for $\lambda < 1.01$ deviate from the variational ones, because the length of the bound state exceeds the finite size. The gap behavior qualitatively agrees with that of the periodic system, and is found to obey

$$E_{\rm gap}(\lambda) - E_{\rm gap}(1) \simeq (\lambda-1) + 1.44 \times (\lambda-1)^{2/3}. \tag{10}$$

This behavior is what is expected by the following analysis in the continuous limit of the model.

We start by rewriting the variational bases and the representation of the Hamiltonian given by eq. (8) into the momentum space. Since the wave length is defined to be sufficiently larger than the lattice constant in the limit, we consider the case of wave number $k \to 0$. We take into account up to the k^2 order for the diagonal part, and the leading order for the off-diagonal part. Then we obtain eigenvalue equations of the following Hamiltonian.

$$H(\lambda) = \epsilon_0 + (\lambda-1) - \frac{1}{2m}\frac{d^2}{dx^2} + \frac{3}{4}(\lambda-1)x \tag{11}$$

Here, x is a distance between a kink and an antikink, m is an effective mass for an antikink, the constant term $\epsilon_0 = E_0(\lambda) + E_{\rm gap}(1)$ for $E_0(\lambda)$ is the ground state energy. The third term of eq. (11) is a kinetic energy of an antikink, and the fourth term is a triangular potential expressing the energy loss by the singlet dimers between a kink and an antikink. Within the first approximation that an antikink is a free spin, the mass is 1 ($m = 1$). In the exact continuous model, on the other hand, structure of an antikink only renormalizes the mass as $m(\lambda)$, as far as the size of an antikink is negligible compared with the length of the bound state.

The eigenvalue equation $H\Psi = E\Psi$ always gives bound states irrespective of λ. This means that a kink and an antikink always form a bound state for $\lambda > 1$. They collapse to a triplet state on a λ bond in the limit $\lambda \to \infty$. The wave function of the ground state of eq. (11) is given by the Airy function with the eigenvalue E:

$$E - \epsilon_0 = (\lambda - 1) + \frac{1}{2}\left(\frac{9}{4m}\right)^{1/3}(\lambda - 1)^{2/3}\tilde{E} \qquad (12)$$

with $\tilde{E} = 2.33816$.[13] We also plot this expression in Fig. 5 with the mass $m = 1.21$, the value estimated at $\lambda = 1$,[10] though there is not a clear difference with the estimates using $m = 1$. This line coincide with the variational results for λ close to 1, but it shifts upward as λ increases. It suggests that the renormalized mass $m(\lambda) > m(\lambda = 1) = 1.21$. An averaged length of the bound state is proportional to $(\lambda - 1)^{-1/3}$.

We also calculated the magnetic susceptibility of finite systems ($N = 6$ and 7) with periodic boundary conditions. All the eigenvalues were calculated by the numerical diagonalization. Therefore the numerically exact values were obtained. Figure 6 shows the temperature dependence of the susceptibility for $\lambda = 1.00, 1.06, 1.10$.

Peak position shifts toward the high temperature side, which is caused by the enhanced spin gap with increasing λ. We consider the present data is enough to explain the thermodynamic limit for $\lambda = 1.06$ and 1.10, since the length of the bound state is within the finite size.

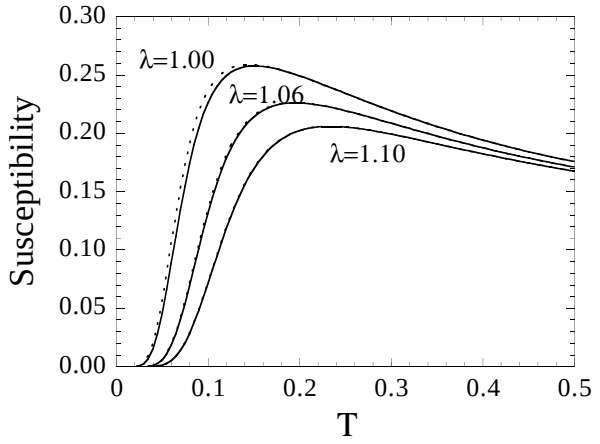

FIG. 6. Uniform susceptibility per spin calculated for $\lambda = 1, 1.06$ and 1.10 by the exact diagonalization of the finite systems with the periodic boundary conditions. The sizes of the systems are $N = 6$(the dashed line) and 7(the continuous line). As λ increase, size dependences become weak.

In summary, we have investigated the Δ chain with the dimerized λ-bond strength increased by a lattice distortion. For the $\lambda > 1$, the gap was found to obey $(\lambda - 1) + 1.44(\lambda - 1)^{2/3}$; the first term is contributed by a kink and the latter is by an antikink. Only 6% change of the bond strength may cause the gap doubled. Therefore care must be paid for the comparison with the experimental results. Analyses on the case of $\lambda < 1$ and the detailed derivation of the continuous limit will be reported elsewhere.

Recently, Chitra et al investigated the 1-dimensional J_1-J_2 model with the bond alternation, and found that the gap behaves with $\delta^{2/3}$ with the alternation parameter δ.[14] We consider it is the same physics with the present model that a kink-antikink bound state is formed by the potential proportional to the δ times distance between a kink and an antikink, which leads to the gap with exponent 2/3.

Authors would like to thank Professor Kenn Kubo and Professor Atsushi Oshiyama for valuable discussions. They also acknowledge thanks to Professor Hidetoshi Nishimori for his diagonalization package, Titpack Ver. 2. Computations were performed on Facom VPP500 at the ISSP, University of Tokyo.
